ABSTRACT—Trauma outcomes are improved by protocols for substantial bleeding, typically activated after physician
evaluation at a hospital. Previous analysis suggested that prehospital vital sign contents patterns indicating the presence
or absence of substantial bleeding. In an observational study of adults (aged ≥18 years) transported to level I trauma
centers by helicopter, we investigated the diagnostic performance of the Automated Processing of the Physiological Reg-
istry for Assessment of Injury Severity (APPRAISE) system, a computational platform for real-time analysis of vital signs,
for identification of substantial bleeding in trauma patients with explicitly hemorrhagic injuries. We studied 209 subjects
respectively and 646 retrospectively. In our multivariate analysis, prospective performance was not significantly different from
retrospective. The APPRAISE system was 76% sensitive for 24-h packed red blood cells of 9 or more units (95% confi-
dence interval, 59% – 89%) and significantly more sensitive (P < 0.05) than any prehospital Shock Index of 1.4 or higher;
sensitivity, 59%; initial systolic blood pressure (SBP) less than 110 mmHg, 50%; and any prehospital SBP less than 90
mmHg, 50%. The APPRAISE specificity for 24-h packed red blood cells of 0 units was 87% (88% for any Shock Index ≥ 1.4,
88% for initial SBP <110 mmHg, and 90% for any prehospital SBP <90 mmHg). Median APPRAISE hemorrhage notification
time was 20 min before arrival at the trauma center. In conclusion, APPRAISE identified bleeding before trauma center
arrival. En route, this capability could allow medics to focus on direct patient care rather than the monitor and, via advance
radio notification, could expedite hospital interventions for patients with substantial blood loss.

KEYWORDS—Trauma, hemorrhage, massive transfusion, decision-support systems, prehospital emergency care

INTRODUCTION

Background

Hemorrhage is recognized as the leading treatable cause of death after injury (1). Improved outcomes in trauma patients
have been shown when trauma centers apply specific protocols for patients with substantial bleeding (2, 3). These protocols
encompass damage-control resuscitation, including aggressive measures to avoid coagulopathy (via permissive hypotension
that slows blood loss, adequate restoration of coagulation

Our group was interested in whether it would be feasible to identify patients with substantial bleeding before arrival at the hospital, without relying on testing or expertise that is normally hospital based, such as sonography or laboratory testing. Growing evidence shows that assessment of multiple vital signs together may be more effective than univariate approaches for detecting hemorrhagic hypovolemia (7, 8). In addition, there have been encouraging reports of computational techniques (9, 10) to account for the fact that high-acuity trauma patients demonstrate complex temporal fluctuations in their prehospital vital signs (11–13), and to identify unreliable vital signs (14), because spurious measurements are so common (15–18).

In this report, we evaluate the hypothesis that it is feasible to identify patients with substantial 24-h PRBC transfusion requirements by automated analysis of prehospital vital signs. To test this prospectively, a specialized real-time computing platform was developed and deployed into an active prehospital operation (19). If it is feasible to identify patients with substantial bleeding by automated analysis of prehospital vital signs, there might be improved en route care as well as in-hospital care. En route, caregivers could focus more on patient care rather than split attention with reexamining and reevaluating the vital sign monitor. The automated system could notify the caregivers when the vital signs were statistically consistent with bleeding and display an on-screen checklist of expected responses. The receiving hospital could be provided with advance radio notification, offering a head start for careful preparation of a patient with major hemorrhage, for example, prewarming of the patient’s bay (to prevent hypothermia), preparation of fresh frozen plasma for immediate transfusion, and mobilization of surgical assets (for early surgical intervention).

**METHODS**

**Setting and study population**

We examined a convenience sample of adult (aged ≥18 years) trauma patients transported by air emergency medical service (EMS) to participating level I trauma centers. With institutional review board approval, we collected a prospective data set from Boston MedFlight (BMF, Bedford, Mass) and compared the findings with an archival data set originally collected from Memorial Hermann Life Flight (MHLF, Houston, Tex) by Cooke et al. (20) and Holcomb et al. (21). In both data sets, we analyzed all subjects with at least one recorded non-zero systolic blood pressure (SBP). Patients who died before hospital admission (e.g., in the emergency department) were excluded from analysis, because resuscitation was often terminated before large-volume PRBC transfusion could be completed, regardless of whether or not the patient had significant hypovolemia.

Our primary study outcome was 24-h PRBC transfusion volume in patients with hemorrhagic injury, defined as a documented hemorrhagic injury that unequivocally caused some loss of blood (laceration or fracture of a solid organ; documented hematoma within the thorax, peritoneum, retroperitoneum, or pelvis; vascular injury that required operative repair; or limb amputation) and PRBC transfusion within 24 h. Patients who received PRBCs but lacked a documented hemorrhagic injury were excluded from the primary analysis because, in the absence of an explicitly hemorrhagic injury, it was challenging to determine whether the transfusion was clinically indicated. Whether the patient had documented hemorrhagic injury was determined by automated text search, searching for injuries that met the aforementioned criteria (records were also jointly reviewed by two investigators, J.L. and A.T.R., who confirmed that the automated text search had not omitted any applicable hemorrhagic injuries nor included nonhemorrhagic injuries).

The excluded patients who lacked explicitly hemorrhagic injuries were reinccluded and analyzed in a sensitivity analysis (see Appendix, Supplemental Digital Content 1, at http://links.lww.com/SHK/A267).

**Vital sign data processing**

For the prospective cohort, we deployed the APPRAISE (Automated Processing of the Physiological Registry for Assessment of Injury Severity [19]) system onto two active BMF helicopters between February 5, 2010, and December 31, 2012. The APPRAISE system consists of a Propaq 206 patient monitor (Welch-Allyn, Beaverton, Oreg) networked to the GoBook ultracompact ruggedized personal computer (General Dynamics Itronix, Sunrise, Fla) running analytic algorithms developed for this research project (19). As a practical matter, this meant that all vital sign data processing and analyses for BMF were done automatically and in real time.

The following routine vital signs were monitored by the Propaq 206 monitor: heart rate (HR), respiratory rate (RR), oscillometric SBP, and pulse pressure (PP), the difference between SBP and diastolic blood pressure). The APPRAISE software created an electronic record of the Propaq data, analyzed the vital sign data in real time using algorithms described below and archived the results. The results of the automated analysis were not visible to the flight crew so that the investigational system would not affect clinical decision making (this was a matter of human subject protection for a diagnostic system that had not yet been validated during clinical operation).

The retrospective data originally had been collected onboard MHLF helicopters between August 2001 and April 2004 using a personal digital assistant networked to a Propaq 206 patient monitor to archive the vital sign data (21). Subsequently, those data were uploaded to our data warehousing system (22) and analyzed offline.

We analyzed the prospective and the retrospective Propaq 206 data using the exact same computational methodology. First, the automated algorithms identified and excluded unreliable vital sign measurements (Fig. 1). The reliability
algorithms for HR and RR involved analysis of the electrocardiography (ECG) and impedance pneumography waveforms. This allowed us to discriminate between a clean source signal versus an unreliable segment caused by signal artifacts (23, 24). The SBP and PP reliability algorithms assessed signal quality by analyzing the relationship between systolic, diastolic, and mean arterial pressures and by comparing HR measured by ECG versus HR measured by oscillometry (22). Studies on the mechanism of trauma, prehospital factors (elapsed time since injury, volume of resuscitation, endotracheal intubation, duration of transport), and anatomy of the injuries based on the trauma registry Abbreviated Injury Scale scores. Two-sided values of $P < 0.05$ were considered as statistically significant.

**RESULTS**

Of the 999 patients with electronic data available (MHLF, 757; BMF, 242), we excluded 22 who lacked a non-zero blood pressure measurement (MHLF, 20; BMF, 2) and 33 who did not survive to admission (MHLF, 27; BMF, 6). Also, there were 89 patients who received 24-h PRBC transfusion while lacking explicitly hemorrhagic injuries (MHLF, 64; BMF, 25); these patients were examined in the sensitivity analysis (see Appendix, Supplemental Digital Content 1, at http://links.lww.com/SHK/A267). Table 1 describes the primary study population.

**Correlation of basic vital signs and 24-h PRBC volume**

In the MHLF data set, SBP, PP, HR, and RR were significantly ($P < 0.001$) correlated with 24-h PRBC transfusion volume: $\rho = -0.32$, $\rho = -0.36$, $\rho = +0.24$, and $\rho = +0.24$, respectively.

In the BMF data set, SBP ($P < 0.001$) and PP ($P < 0.01$) were significantly correlated with 24-h PRBC transfusion volume: $\rho = -0.30$ and $\rho = -0.23$, respectively. Heart rate showed a nonsignificant trend ($P = 0.051$), with $\rho = +0.14$, whereas RR was not significantly correlated.

Incidentally, there were three subjects who received prehospital needle decompression, and all received hemorrhage notifications during transport (24-h PRBC volumes for these subjects were 0, 4, and >20, respectively).

Timelines

Figure 2 illustrates prehospital timelines for all subjects with 24-h PRBC volume of 9 or more units, showing the timing of blood pressure measurements, of APPRAISE hemorrhage notifications, and episodes of hypotension (SBP <90 mmHg). The median notification time after the start time of transport was 6 min (interquartiles 4–16) for MHLF and 10 min for BMF (interquartiles 8–40). The median notification time before arrival at the hospital was 17 min for MHLF and 52 min for BMF, and the difference was largely caused by shorter transport times for MHLF (the median transport time for subjects with 24-h PRBC volume ≥9 units was 28 min [interquartiles 24–36] for MHLF and 65 min [interquartiles 35–78] for BMF). Combining the two populations, APPRAISE notification occurred in the first half of the transportation in 73% of the cases.

Nine subjects returned to APPRAISE-negative status after a hemorrhage notification: six MHLF subjects who were actually false positive (i.e., 24-h PRBC = 0) and three BMF subjects who were true positive (i.e., 24-h PRBC ≥1) and received prehospital PRBC transfusion.

Multivariate logistic regression

Using logistic regression to model the likelihood of APPRAISE hemorrhage notification as a function of 24-h PRBC transfusion volume further demonstrated that the results were similar in both data sets (Fig. 3). Each PRBC unit transfused was associated with a 43% (95% CI, 30–57%) increase in the odds of APPRAISE hemorrhage notification for MHLF and a 44% (95% CI, 24–67%) increase for BMF. The odds ratio of APPRAISE notification per unit of PRBC transfused was not significantly different between the two data sets (i.e., BMF versus MHLF) when fitting a regression model to the pooled data set (P = 0.635). However, there was a nonsignificant trend toward a lower overall likelihood of hemorrhage notification in the BMF data set when compared with the MHLF data set (P = 0.053), including a lower likelihood of hemorrhage notifications in patients without bleeding (24-h PRBC = 0) and with substantial bleeding (24-h PRBC ≥9), which is apparent in the offset between the two regression curves (Fig. 3). Note that the specificities and sensitivities extracted from Figure 3 are slightly different from those reported in Table 2 because of the nature of the regression fit.

We investigated the factors associated with whether subjects received an APPRAISE hemorrhage notification; see univariate and multivariate logistic regression analyses in Table 3. In multivariate analysis, four independent factors were significant predictors of whether the patient received an APPRAISE notification: increasing 24-h PRBC volume, increasing severity

the proportion of APPRAISE-positive subjects exhibited an increasing trend in both the MHLF and BMF studies. In the pooled data set (MHLF and BMF), sensitivities for 24-h PRBC transfusion volume of 9 or more units for APPRAISE notification, SI of 1.4 or higher, initial SBP less than 110 mmHg, and any hypotension (SBP <90 mmHg) were 76% (59%–89%), 59% (41%–75%), 50% (32%–68%), and 50% (32%–68%), respectively, and we found that the sensitivity of APPRAISE notification was significantly higher than SI of 1.4 or higher (P = 0.014), initial SBP less than 110 mmHg (P = 0.007), and any hypotension, that is, SBP less than 90 mmHg (P = 0.007). The sensitivities of APPRAISE notification for 24-h PRBC transfusion volume of 9 or more units were similar for the MHLF versus BMF data sets: 76% (55%–91%) and 78% (40%–97%), respectively.

In the pooled data set (MHLF and BMF), specificities for 24-h PRBC transfusion volume of 0 units (i.e., no blood transfusion at all) for APPRAISE notification, SI of 1.4 or higher, initial SBP less than 110 mmHg, and any hypotension (SBP <90 mmHg) were 76% (59%–89%), 59% (41%–75%), 50% (32%–68%), and 50% (32%–68%), respectively, and we found that the specificity of APPRAISE notification was significantly different from initial SBP less than 110 mmHg or any prehospital SI of 1.4 or higher. Compared with any prehospital SBP less than 90 mmHg, APPRAISE notification showed a significantly lower specificity (P < 0.05), although the absolute magnitude of the difference was 3%. The specificities of APPRAISE notification for 24-h PRBC transfusion volume of 0 units were 86% (83%–89%) for the MHLF data set and 90% (85%–94%) for the BMF data set. In the pooled data set, negative predictive values (24-h PRBC transfusion volume = 0 units vs. ≥1 unit) for APPRAISE notification, SI of 1.4 or higher, initial SBP less than 110 mmHg, and any hypotension (SBP <90 mmHg) were similar: 94% (92%–96%), 92% (90%–94%), 92% (90%–94%), and 92% (90%–94%), respectively.
of chest injury, longer flight duration, and younger age. Neither abdominal, nor head, nor extremity injury severity had a significant association with false-negative alarms. Prehospital PRBC transfusion was only found in the BMF cohort, and those patients had a significantly increased risk of APPRAISE hemorrhage notification.

**DISCUSSION**

This investigation demonstrated that there was a strong association between 24-h PRBC transfusion volume and abnormal prehospital vital signs, and that the majority of patients with large transfusion requirements could be distinguished from other trauma patients using techniques for time series and multivariate analysis. The automated APPRAISE system required neither oversight nor input by the flight crew; it operated wholly autonomously, only requiring that the flight crew use their Propaq transport monitor as per standard procedure. The performance of the APPRAISE algorithms for early identification of patients with 24-h PRBC of 9 or more units was quite similar in actual prospective real-time use (the BMF data set) versus simulated real-time use (the MHLF data set).

**Potential benefits of prehospital identification of substantial bleeding**

Automated functionality that reliably provides a notification whenever important patterns develop would permit the caregiver to focus much more on the patient (e.g., better pain control, better management of retching patients who could aspirate, etc.) and not constantly split attention between the patient and the travel monitor. Consistent fully automated detection of hypovolemic vital signs may be most clinically valuable if the EMS caregiver is inexperienced, fatigued, or distracted.

With reliable notification that a bleeding patient is about to arrive, the receiving facility could prepare for hemorrhage-specific management. Today’s typical practice involves a trauma team evaluation—postarrival—before deciding whether to activate protocols for substantial bleeding (2). At best, this adds a small delay to care and, in some cases, resultant delays can be substantial. In one report describing the benefits of an institutional protocol for substantial bleeding, interventions such as transfusion of fresh-frozen plasma were not initiated for several hours in many cases (6). By analogy, the common practice of activating the cardiac catheterization team when the prehospital ECG shows ST-elevation myocardial infarction in a patient with chest pain illustrates the potential value of readying the hospital for an exsanguinating patient based on a simple objective prehospital indicator: by initiating in-hospital preparations based on prehospital notification, the time delay to percutaneous coronary intervention can be reduced (32). Of note, cardiologists still conduct expert evaluations before undertaking catheterization, and prehospital notification does not remove clinical authority from hospital caregivers.
Physiological interpretation of the findings

At a rudimentary level, this study suggests that patients with massive 24-h blood transfusion requirements demonstrate hypovolemic physiology before hospital arrival. This intuitive finding is consistent with other prediction rules for massive transfusion where hypotension and tachycardia are established predictive factors for massive transfusion (5).

Unlike the other massive transfusion prediction rules, the APPRAISE system only involves vital sign data analyzed during prehospital transport. The APPRAISE system uses well-known statistical techniques, such as time averaging and the SPRT, for analyzing data that fluctuate through time, and it detects hemorrhage by considering the temporal accumulation of evidence. The system does not seek to identify trends through time (e.g., downward drifts in SBP), which may seem counterintuitive, but it has been clearly demonstrated that prehospital vital signs fluctuate substantially frequently without obvious overt directional trends (10–14).

In addition to time series techniques, another common sense principle incorporated in the APPRAISE system was multivariate analysis. Like several prediction rules for massive transfusion (5), the APPRAISE system’s algorithms used the independent diagnostic information from more than one vital sign. This is consistent with recent reports that the SI (the ratio of HR to SBP) is a valuable diagnostic tool for identification of hemorrhage (7, 8). The APPRAISE system identifies hypovolemia by a combination of low SBP, low PP, high HR, and high RR. A minority of the massive transfusion patients were not detected by the APPRAISE system; those generally lacked hypotension (Fig. 2B), suggesting that they were not substantially hypovolemic during transport.

There were also APPRAISE hemorrhage notifications in patients who did not require massive transfusion. These patients were likely hypovolemic during transport yet without the ongoing blood losses that necessitate massive transfusion (of note, among patients who never needed any PRBCs, those who

received an APPRAISE hemorrhage notification had significantly higher average injury severity scores). Whether the alert would offer clinical value in this population without massive transfusion requirements is an open question. As discussed above, the APPRAISE system would not obviate the need for clinical assessments by prehospital and receiving facility personnel. Rather, the system is a tool for optimizing vital sign information, offering automated consistent notification when the patterns suggest hypovolemia, and these patterns are strongly associated with subsequent blood transfusion requirements.

**Limitations**

The study outcome, hemorrhage severity, was quantified by each patient’s 24-h PRBC volume. However, the quantity of PRBCs that a patient actually receives is a function of multiple factors, including the speed and effectiveness of surgical hemorrhage control, and some subjective clinical decision making. The generalizability of the findings, that is, the notification incidence versus 24-h PRBC volume, and their applicability to guiding initial resuscitation may have limitations. Yet, the notable consistency (Fig. 3) between the MHLF and BMF results during aeromedical transport to one and three distinct trauma centers, respectively, suggests that such confounding factors can average out across different trauma systems, yielding consistent relationships between prehospital notification incidence and hemorrhage severity.

The prospective BMF arm of this study was sufficient to demonstrate that the real-time system can perform encouragingly well (seven of nine massive transfusion BMF subjects received a real-time prehospital notification). However, the BMF data set was too small to directly compare test characteristics of the APPRAISE notification versus hypotension or SI.

**CONCLUSIONS**

We conclude that real-time multivariate time series analysis of vital signs is a feasible means of identifying prehospital trauma patients with substantial bleeding, and that prospective investigation of the clinical value of this automated methodology is justified.
